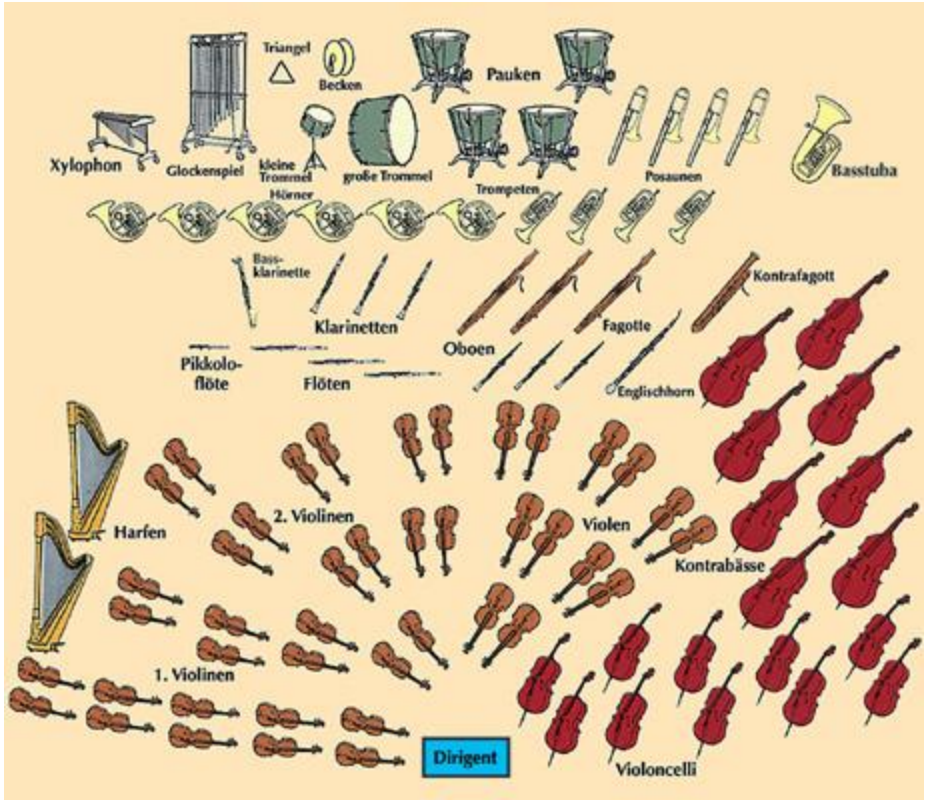
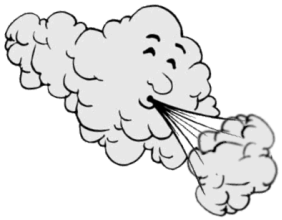
Network Algorithms

Self-Stabilization

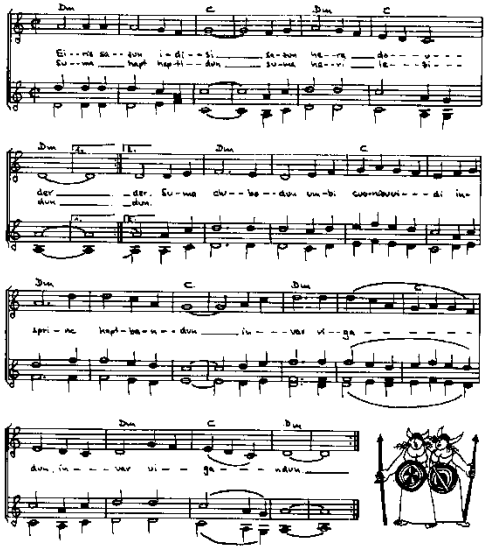
Robust Algorithms: A Concert for the Mayor



A Concert for the Mayor

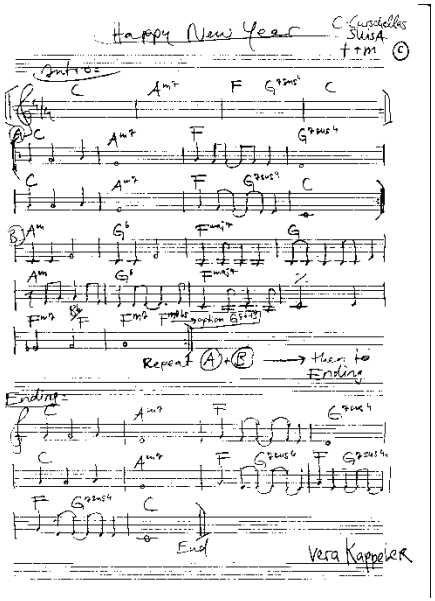


Page 4



Page 22

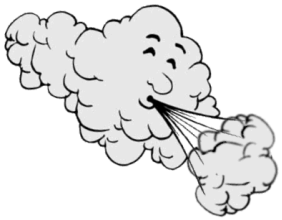
Page 1



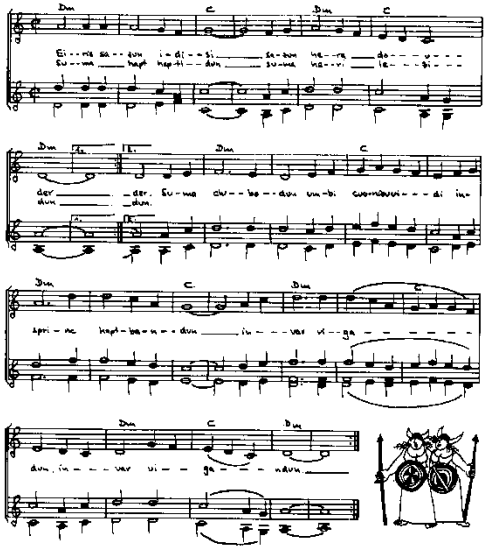
Requirements:

- Play “happy birthday” again and again
- Wind changes pages without players knowing!
- When wind stops, harmonize eventually!

A Concert for the Mayor

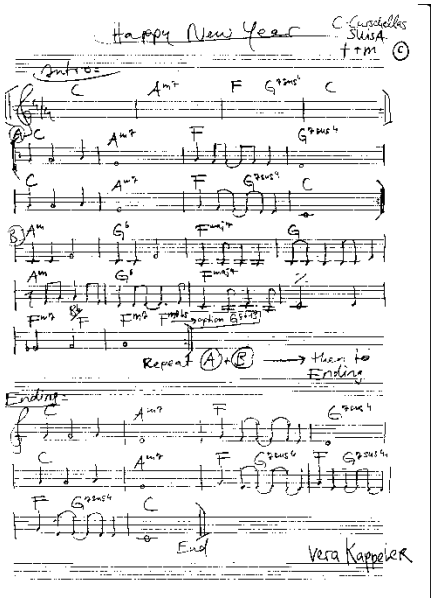


Page 4



Page 22

Page 1



How to achieve?

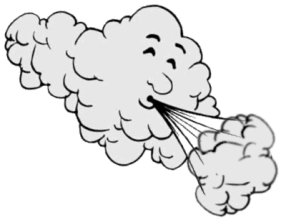
Idea 1: If out of sync, just change to the page of a nearby player!

But what if the neighbor does the same? Do not know who was right! May never converge…

Idea 2: Go to start when asynchrony detected!

But players further away detect it later and restart later! May never converge…

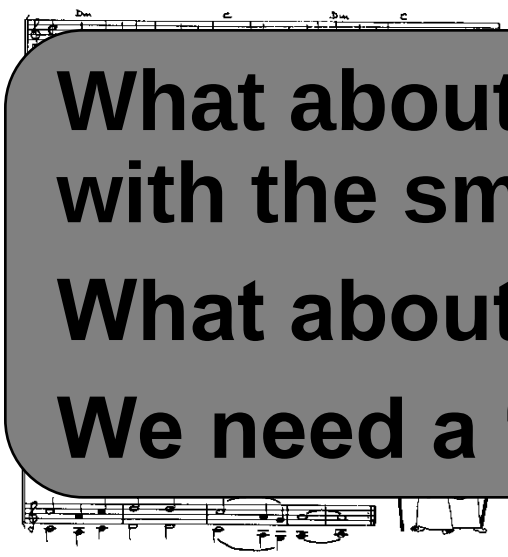
A Concert for the Mayor



Page 4

Page 22

Page 1



What about synchronizing to the neighbor with the smallest page number?

What about…?

We need a "self-stabilizing algorithm"!

How to achieve?

Idea 1: If out of sync, just change to the page of a nearby player!

But what if the neighbor does the same? Do not know who was right! May never converge…

Idea 2: Go to start when asynchrony detected!

But players further away detect it later and restart later! May never converge…

Self-Stabilizing Algorithms

The Vision:

Self-Stabilizing Algorithms

The Vision:

Self-Stabilizing System

A distributed system is self-stabilizing if, starting from an arbitrary initial state, it is guaranteed to converge to a legitimate state. If the system is in a legitimate state, it is guaranteed to remain there, provided that no further faults happen. A state is legitimate if the state satisfies the specifications of the distributed system.

A self-stabilizing system does not have to be initialized: "automatically correct"

The Adversary Model

The adversary can:

- crash nodes
- make nodes behave Byzantine
- even corrupt the volatile memory of a node (without the node noticing)
- corrupt messages on the fly (without anybody noticing)

… but it cannot change the ROM (the algorithm/code)

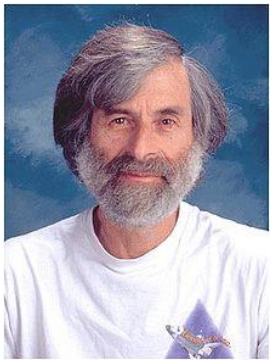
All failures are transient, and eventually all nodes must work correctly again: crashed nodes get resurrected, Byzantine nodes stop being malicious, messages are being delivered reliably, and the memory of the nodes is secure.

Self-Stabilization

Self-stabilizing algorithms pioneered by **Dijkstra** (1973): for example self-stabilizing mutual exclusion.

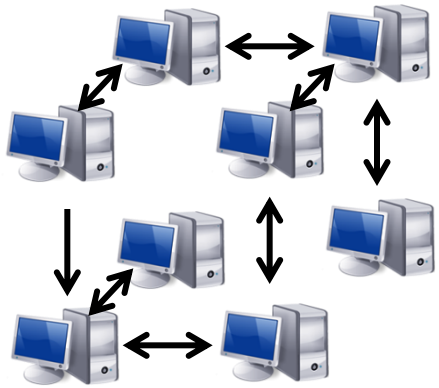
"I regard this as Dijkstra's most brilliant work. Self-stabilization is a very important concept in fault tolerance."

Leslie **Lamport** (PODC 1983)

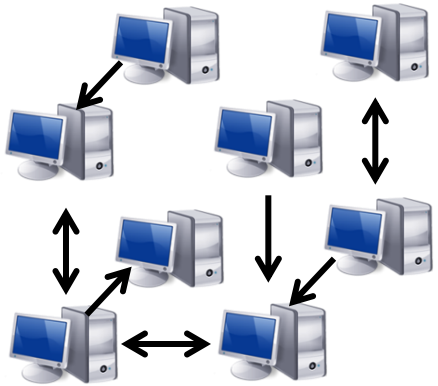


Example: Topological Self-Stabilization

From chaos to order: self-stabilizing distributed datastructure

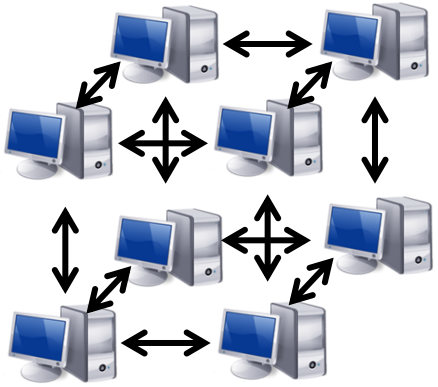


failures, adversary, attack, …



t_0

adversary stops

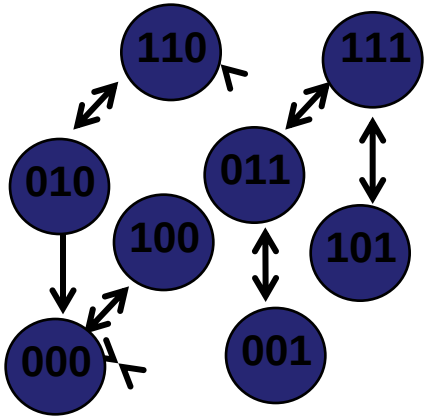


t_0+D

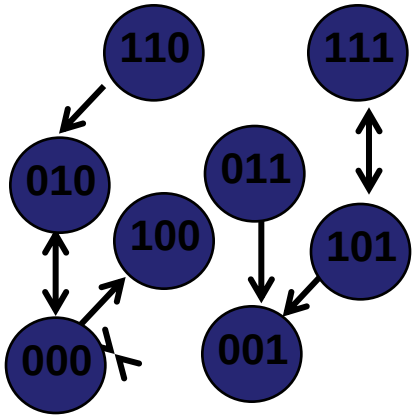
desired structure

Example: Topological Self-Stabilization

Example: Hypercube (log+log)

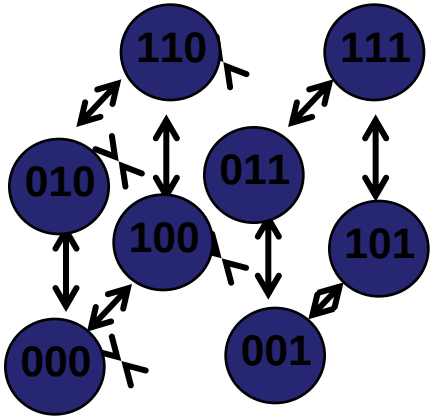


failures, adversary, attack, …



t_0

weakly connected

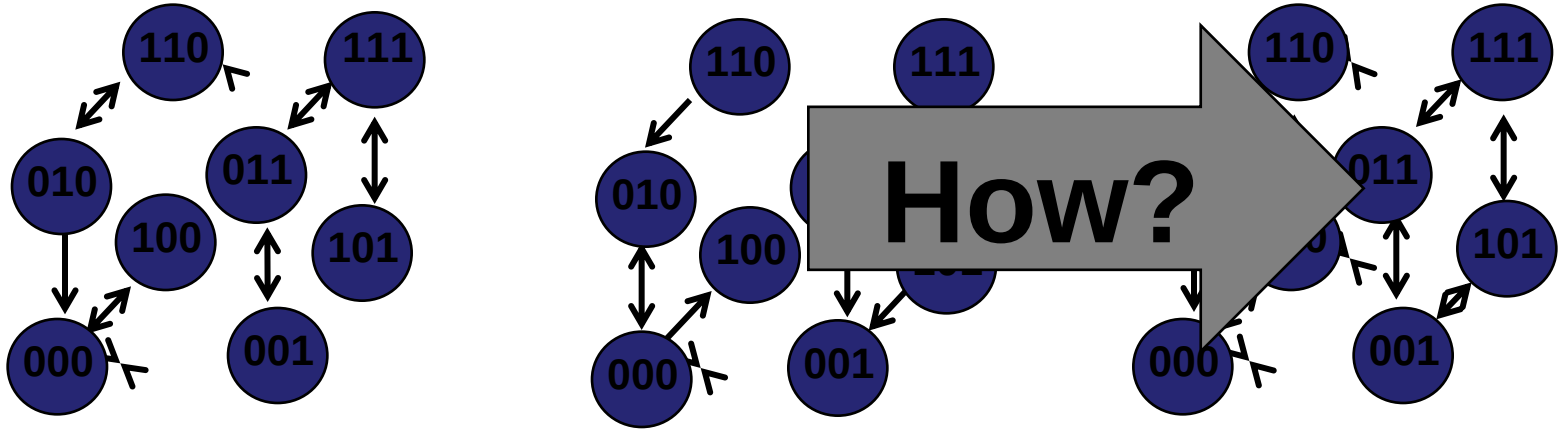


t_0+D

stabilized hypercube

Example: Topological Self-Stabilization

Example: Hypercube (log+log)



failures, adversary, attack, …

t_0

weakly connected

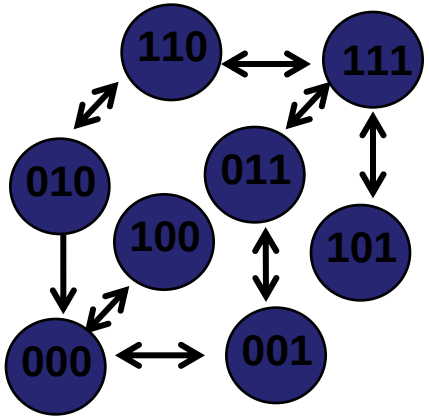
t_0+D

stabilized hypercube

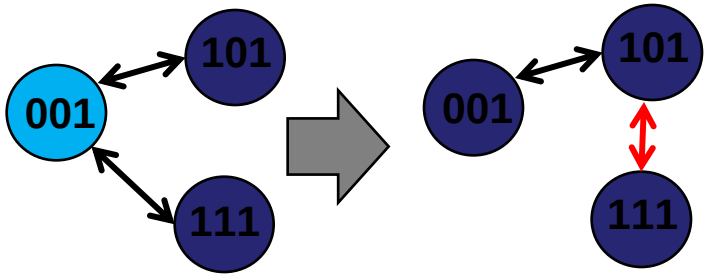
Example: Topological Self-Stabilization

Configuration

- **Constants:** identifiers
- **Variables:** neighborhoods (set of identifiers)
- Union over all nodes

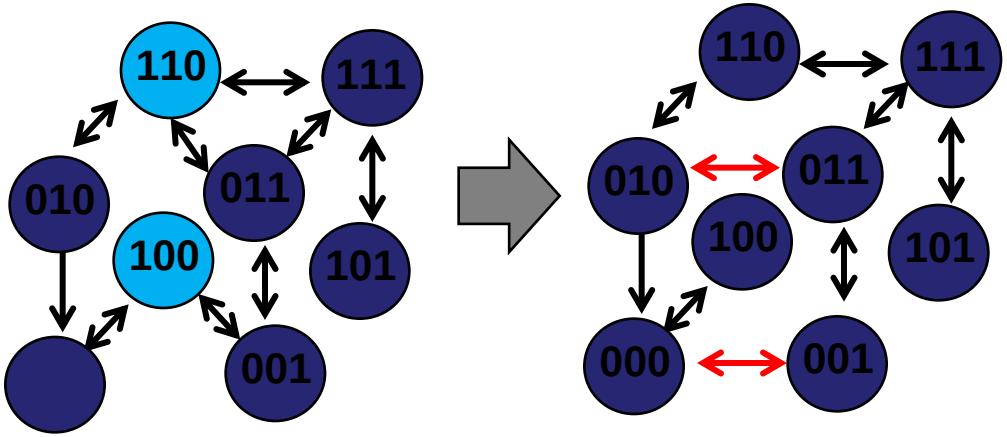


- **Condition:** on local state
- **Action:** propose new link in neighborhood
- Careful: stay connected!



Execution

- **Scheduler:** execute enabled actions
- Gives next configuration
- In parallel, or “scalably”



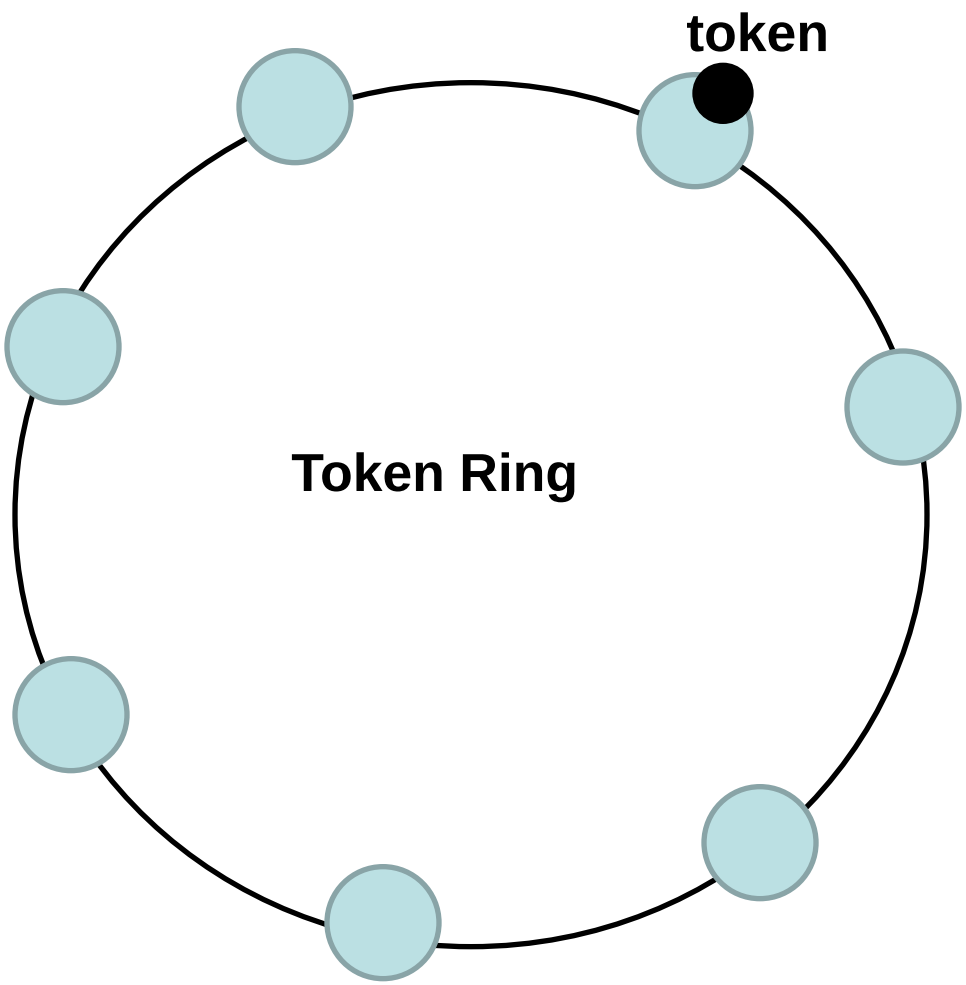
Self-Stabilization

- Convergence: eventually we end up in desired configuration
- Closure: once there, stays there

Time Complexity

The time complexity of a self-stabilizing system is the time that passed after the last (transient) failure until the system has converged to a legitimate state again, staying legitimate.

Self-Stabilizing Token Ring



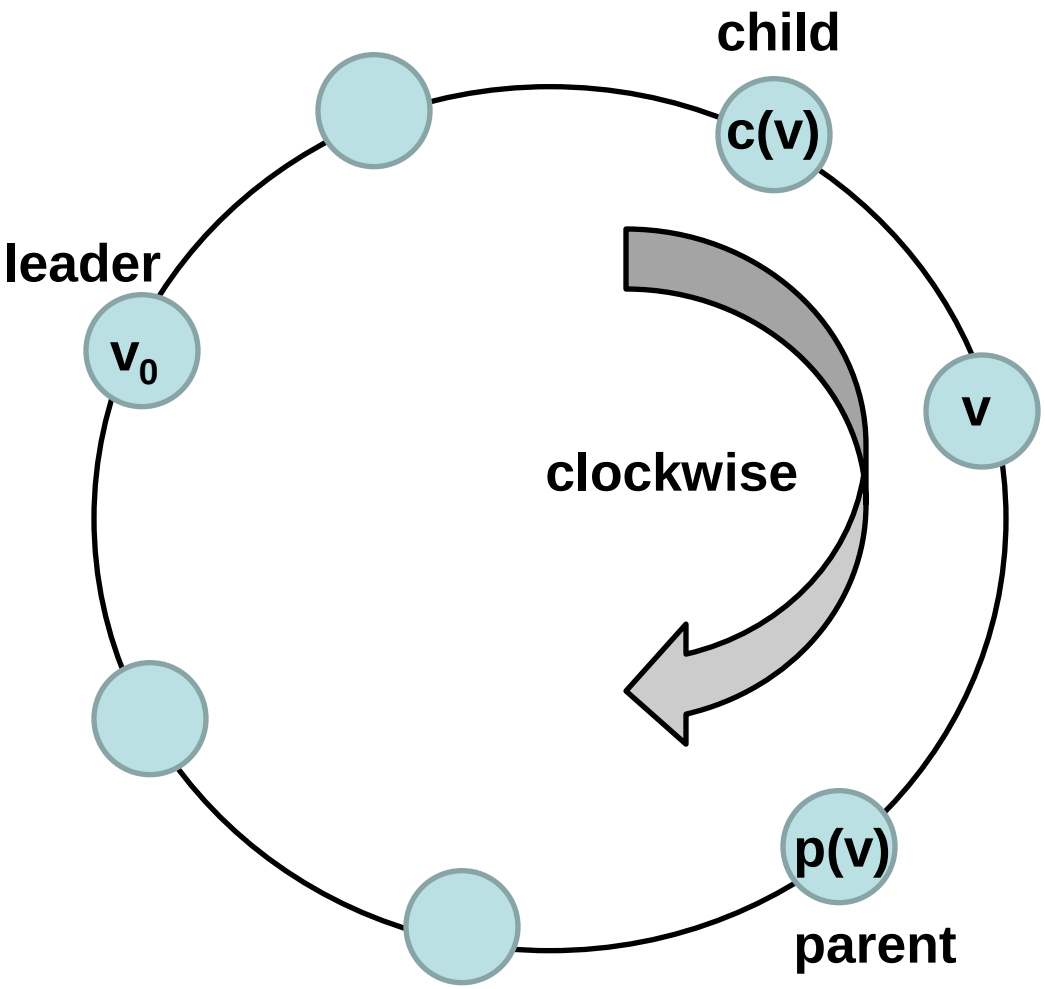
Protocol correct iff exactly one token / active node in ring and token cycles.

Assume:

- topology fixed
- n known
- a leader v_0

How to design self-stabilizing token ring?! Adversary may add and remove many tokens anytime initially!

Self-Stabilizing Token Ring



- Each node is in a state S={1,…,n}
- Each node informs its child continuously about its state

Token Ring

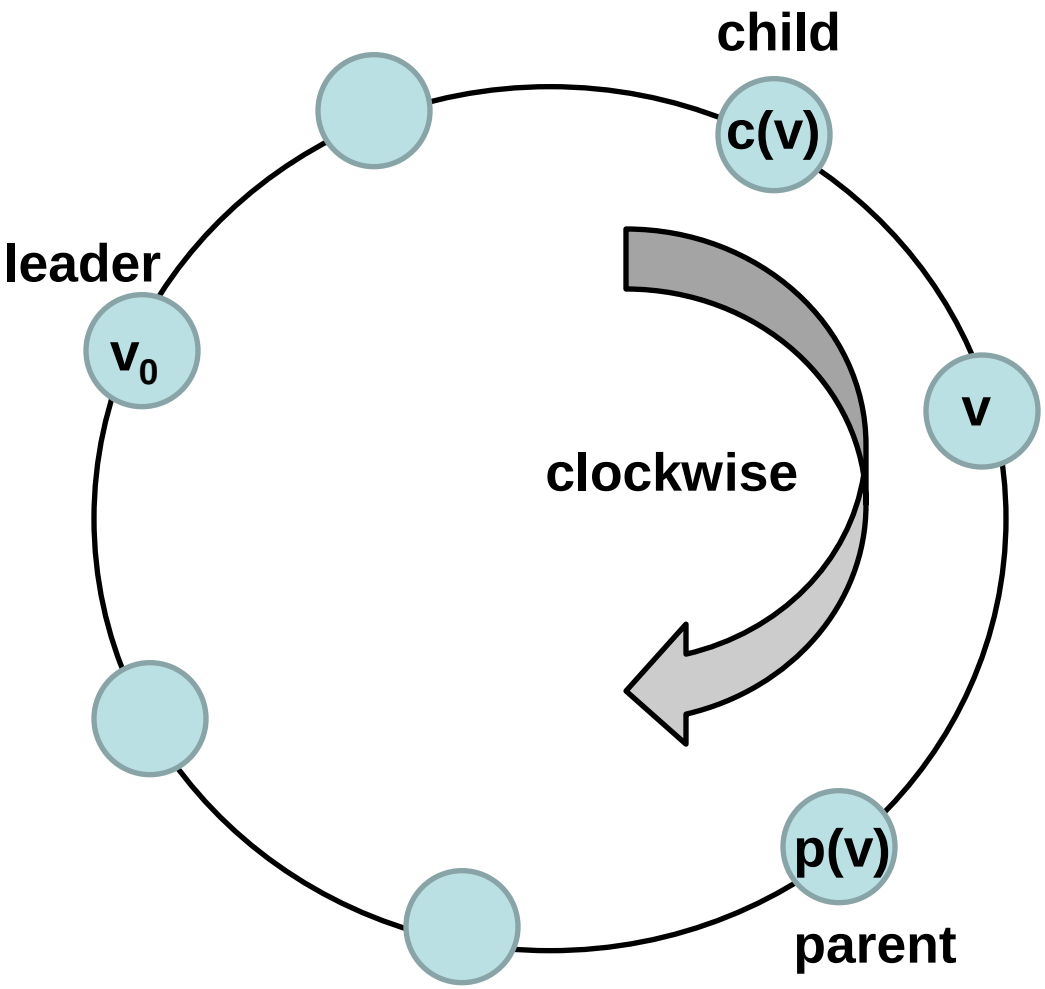
If $v = v_0$ then

  If S(v)=S(p) then

    S(v) := S(v) +1 (mod n)

Else S(v):=S(p)

Self-Stabilizing Token Ring



- Each node is in a state S={1,…,n}
- Each node informs its child continuously about its state

Token Ring

If $v = v_0$ then

  If S(v)=S(p) then

    S(v) := S(v) +1 (mod n)

Else S(v):=S(p)

Leader chooses next ID, all other nodes copy from parent!

Token Ring

The algorithm stabilizes correctly.

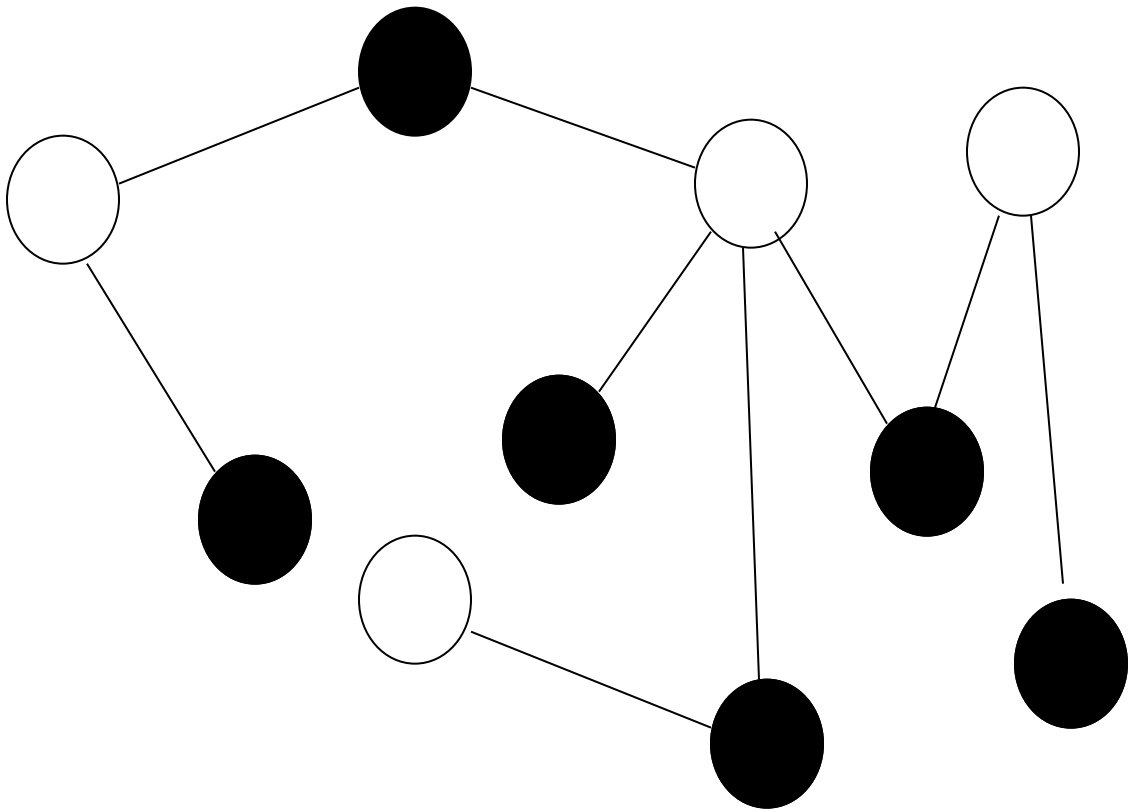
Proof:

- Each node except for leader v_0 will attain and forward the state of its parent.
- The leader can only get the next larger value when its parent has the leader value too.
- At some point the leader will reach a state *s* that no other node had at time *t*0. (There are *n* nodes and *n* states.)
- Then one node after the other will learn the current state of the leader.
- The leader itself does not push the next value until the previous value travelled the entire ring!
- So the system stabilizes after at most *n* time units after the leader increased the value.
- At most one node active at any time: Token passed implicitly with the switching state.

QED

Self-Stabilizing Independent Sets

How to design self-stabilizing Maximal Independent Sets?



Self-Stabilizing Independent Sets

Assume: node have unique IDs

Independent Sets

Every node *v* executes the following code:

1: do atomically (forever)

2: Leave MIS if a neighbor with a larger ID is in the MIS

3: Join MIS if no neighbor with larger ID joins MIS

4: Send (node ID, MIS or not MIS) to all neighbors

5: end do

Why does it work?

Self-Stabilizing Independent Sets

Assume: node have unique IDs

Independent Sets

Every node *v* executes the following code:

1: do atomically (forever)
2: Leave MIS if a neighbor with a larger ID is in the MIS
3: Join MIS if no neighbor with larger ID joins MIS
4: Send (node ID, MIS or not MIS) to all neighbors
5: end do

Why does it work?

Same argument as for our Slow-MIS algorithm.
Only difference: need to run it forever now…
Can I make any local algorithm self-stabilizing?!
Desired criteria?

Transformation

Given:

Any deterministic local algorithm A that computes a solution of a given problem in k synchronous communication rounds.

Output:

A self-stabilizing system with time complexity k, i.e.:

- if the adversary does not corrupt the system for k time units, the solution is stable
- if the adversary does not corrupt any node or message closer than distance k from a node u, node u will be stable (locality)

Transformation

Given:

Any deterministic local algorithm A that computes a solution of a given problem in k synchronous communication rounds.

Output:

A self-stabilizing system with time complexity k, i.e.:

- if the adversary does not corrupt the system for k time units, the solution is stable
- if the adversary does not corrupt any node or message closer than distance k from a node u, node u will be stable (locality)

Any ideas how?

Transformation: Local Checking

- Each node maintains tables for the k different rounds of the execution of A:
  - Store all local variables of the last k rounds
  - Store all messages received for the last k rounds
  - All info that is not known is simply “?”

- Simulate all the *k* phases of the local algorithm *A* in parallel
  - Exchange the above tables forever

- Each node checks whether the received tables from the neighbors as well as the messages are consistent

- Also known as Local Checking

Transformation: Local Checking

- Let $\mathbf{L}^i_u$ be the state of the local variables of node u after round i, and let $\mathbf{m}^i_{uv}$ be the message sent from u to v in round i.

- Each node continuously sends its $\mathbf{L}^i_u$ tables to the neighbors, together with the messages $\mathbf{m}^i_{uv}$.

- Neighbor updates its message table accordingly and sends corresponding messages.

- Proof by induction:
  - At time t_0, nodes correctly initialize their local variables
  - At time t_0+1, they send the correct messages to neighbors
  - At time t_0+2, ...

With this transformation:

design turned from Art to Craft!

Transformation: Local Checking

design turned from Art to Craft!

What is the overhead?

What about randomized algorithms?

Discussion

- How to do it for randomized algorithms?
  - Do not know k, the number of rounds!
  - But can just simulate more rounds, no problem.
  - Careful about adversary: should not compromise randomness of choices (e.g., have nodes produce random bits until it's what he wanted)

- Some additional memory overhead, but usually bearable.
  - Memory overhead depends on k, the number of rounds, which is low.

- Good for mobile environments: if k-neighborhood does not change, nothing changes

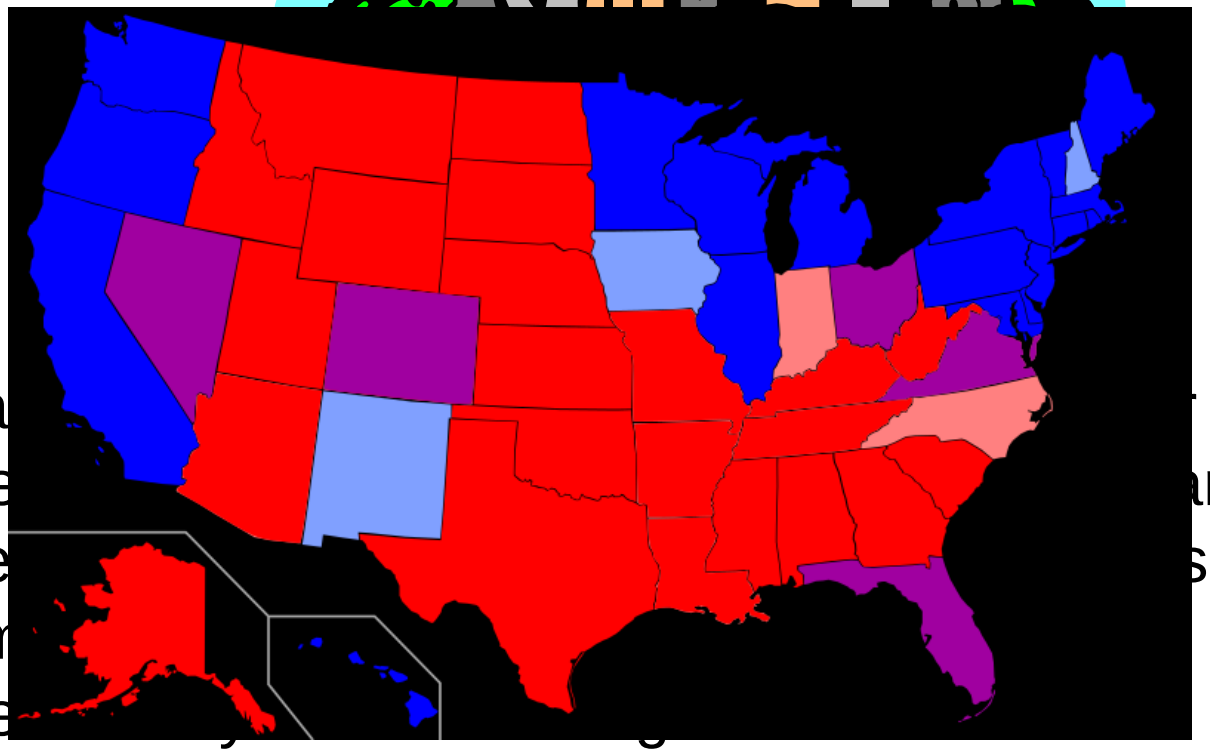
Advanced Stabilization

In a little town, each evening citizens call their friends to ask whether they vote for Democrats or Republicans.
Then they decide themselves for majority (assume odd number of friends).
Does this system «converge» or «stabilize»?

Advanced Stabilization

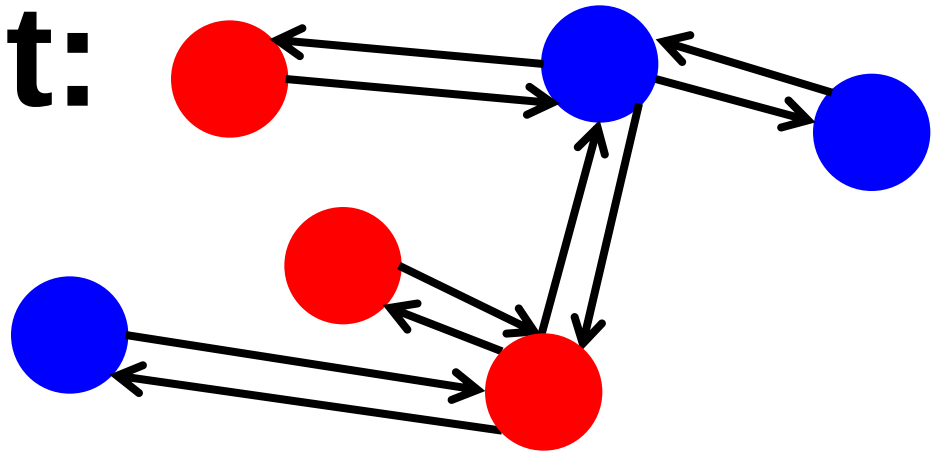
Democratic

Republicans



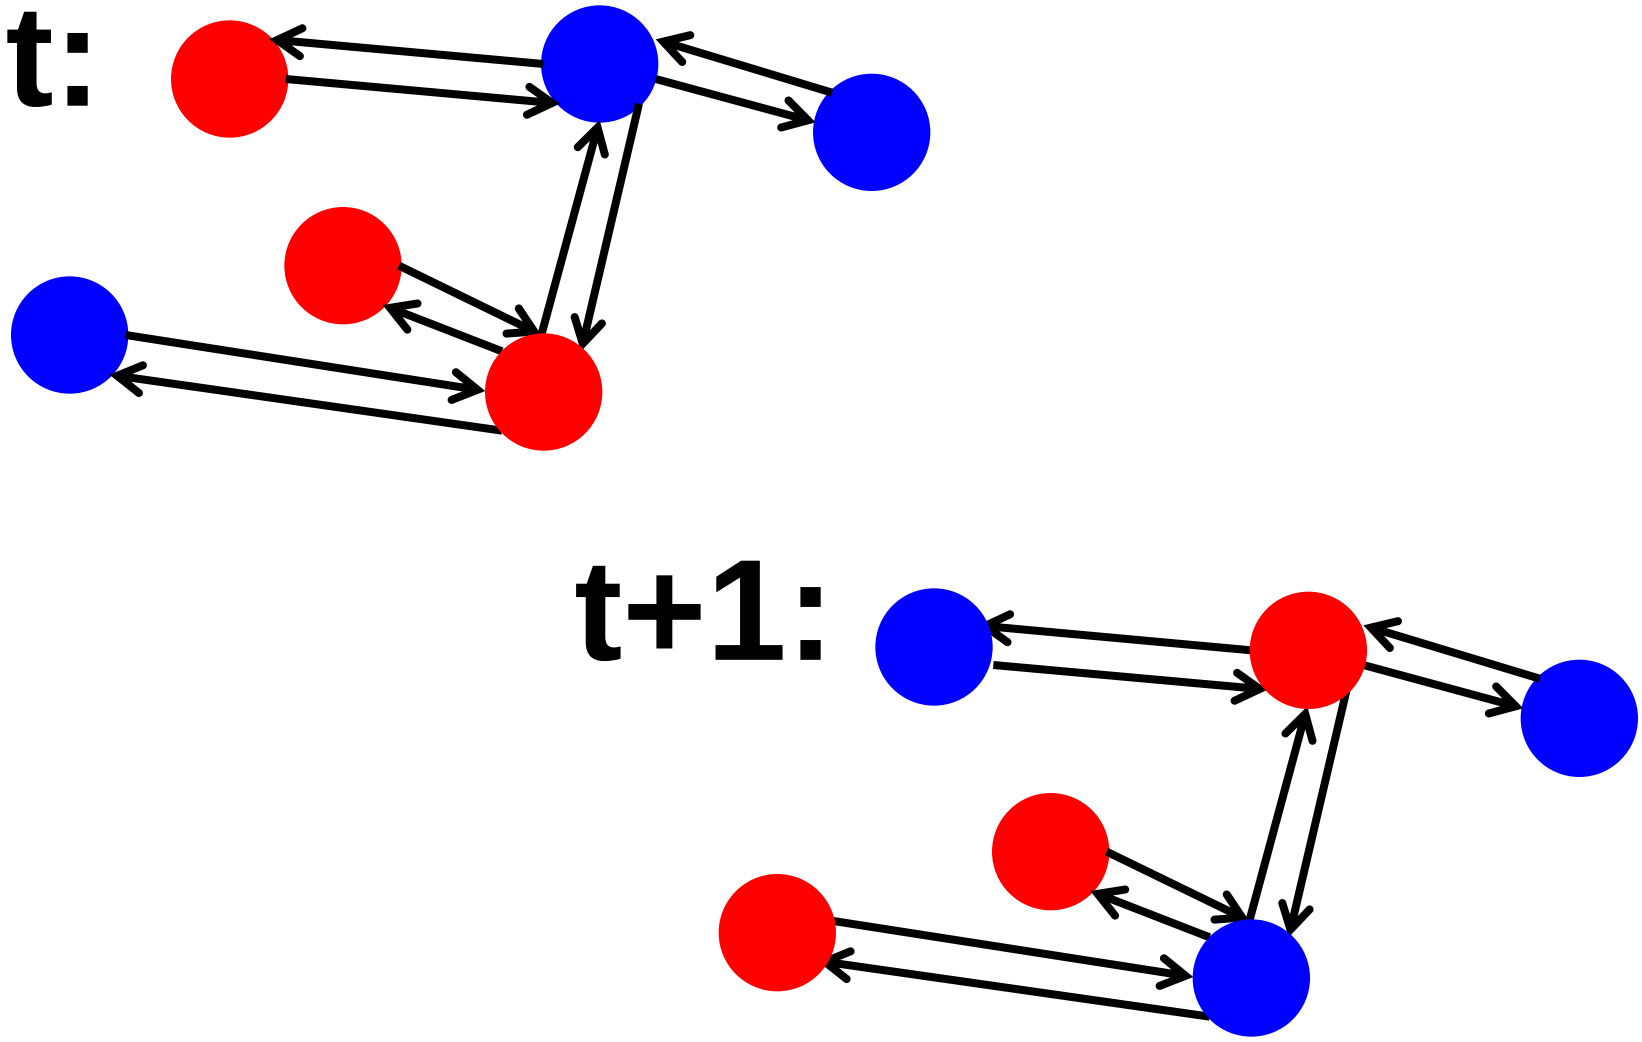
In a friends to ask
whe ans.
The sume odd
num
Doe

Example



t+1:

Example



What do you think?

- Is eventually everybody voting for the same party?
- Will each citizen eventually stay with the same party?
- Will citizens that stayed with the same party for some time, stay with that party forever?
- And if their friends also constantly root for the same party?
- Will this beast stabilize at all? ☺

Democrats / Republicans

Eventually each citizen will vote for the same party every other day.

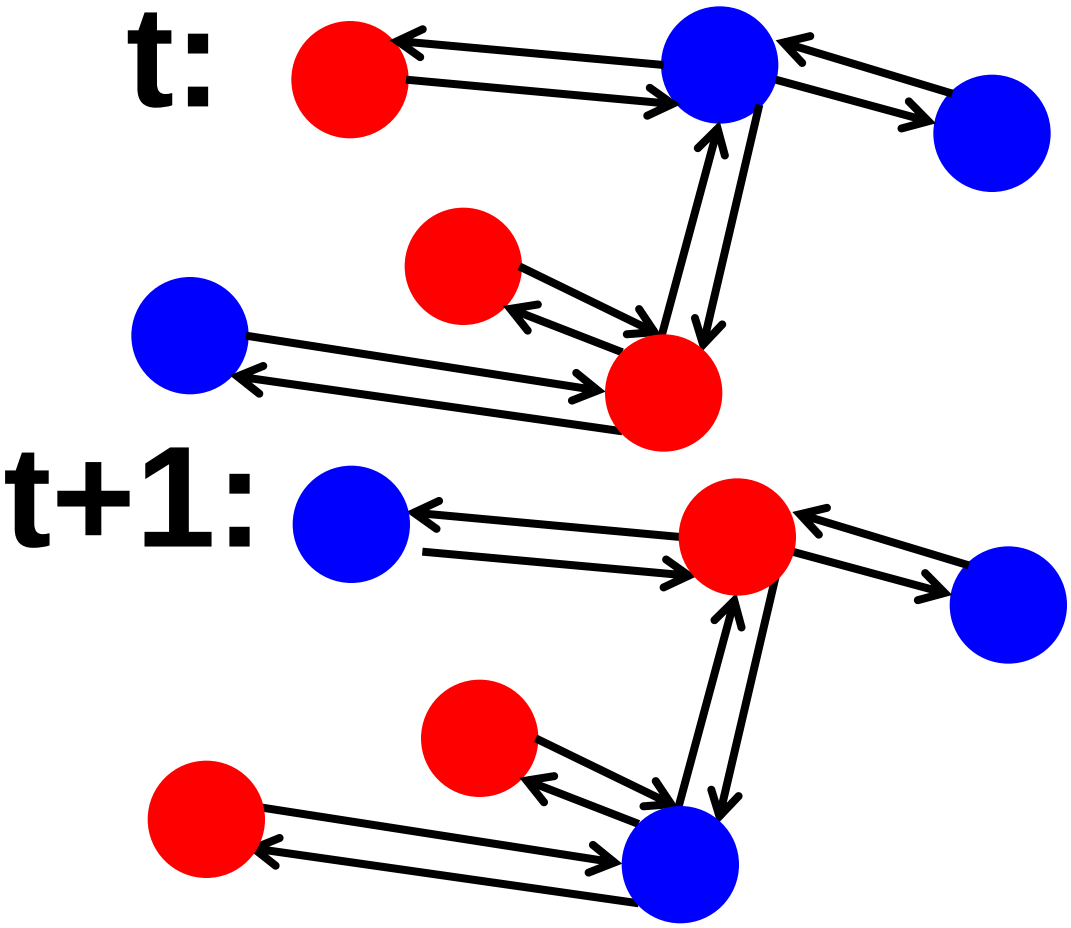
Why?

Democrats / Republicans

Eventually each citizen will vote for the same party every other day.

Why?

- Friendship = directed edges
- Bad edge: to node which did not follow the advisor's opinion: Example?

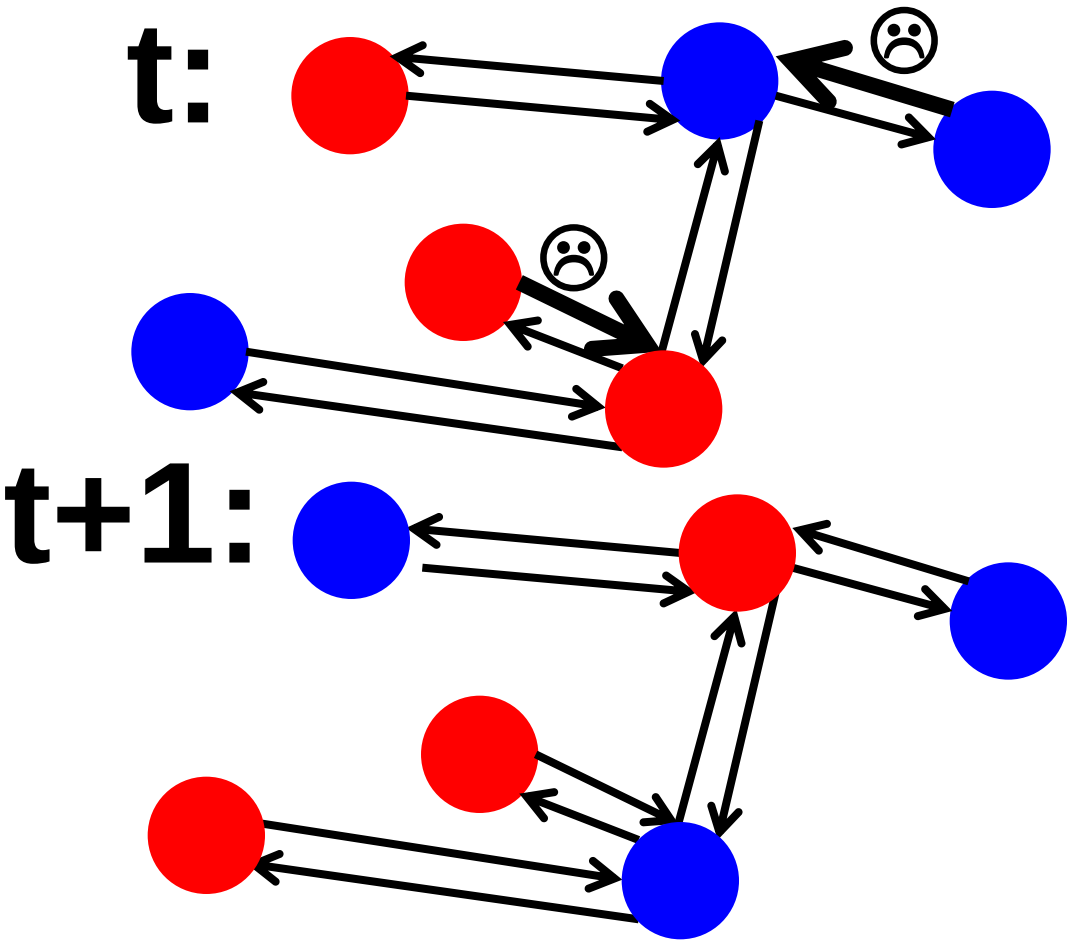


Democrats / Republicans

Eventually each citizen will vote for the same party every other day.

Why?

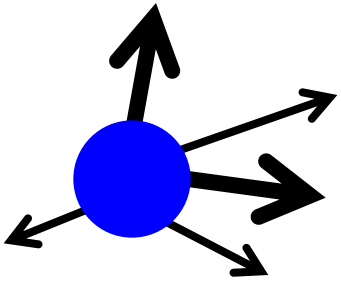
- Friendship = directed edges
- Bad edge: to node which did not follow the advisor's opinion: Example?



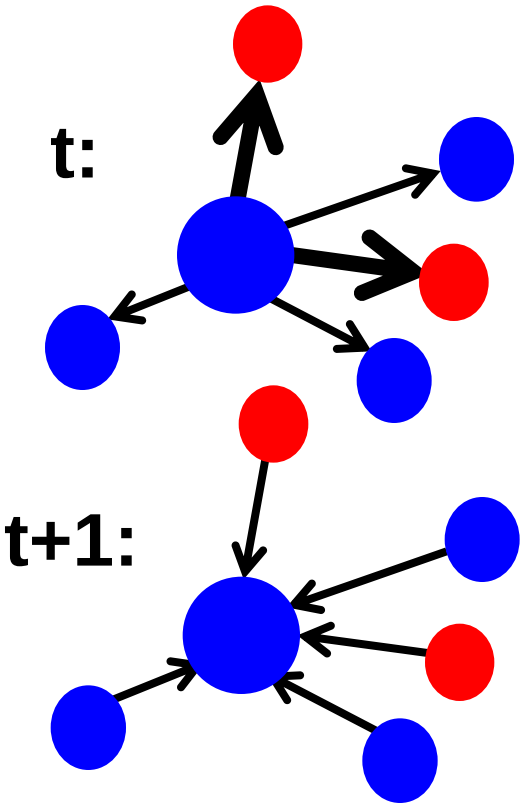
Democrats / Republicans

Eventually each citizen will vote for the same party every other day.

Continued (1)



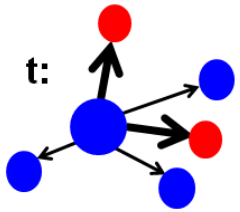
- Consider a citizen c (Democrat) with g good and b bad out-edges on a day t
- So *g* friends of *c* root for the Democrats on day *t*+1, and *b* friends root for the Republicans
- So in evening of *t*+1, *c* will receives *g* recommendations for Democrats, and *b* for Republicans.
- What if g>b, what if g<b?



Democrats / Republicans

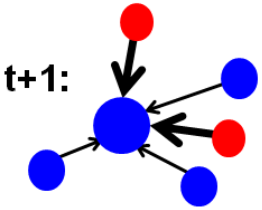
Eventually each citizen will vote for the same party every other day.

Continued (2)



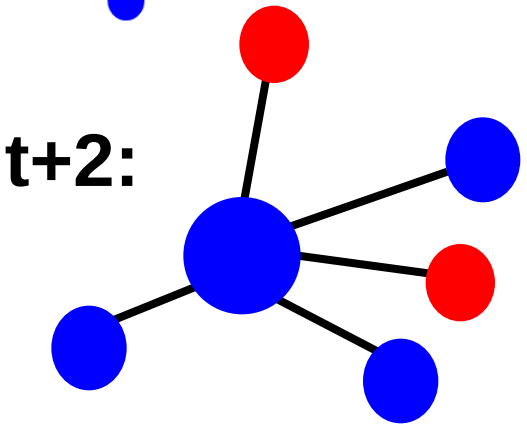
2 bad edges

- If g>b: citizen c will still/again root for the Democrats on day *t*+2. (At time t+1? Unclear!)



2 bad edges

- Note: Good out-edge becomes good in-edge, bad out-edge becomes bad in-edge!



If node chooses same party at t and t+2, number of bad edges stays the same!

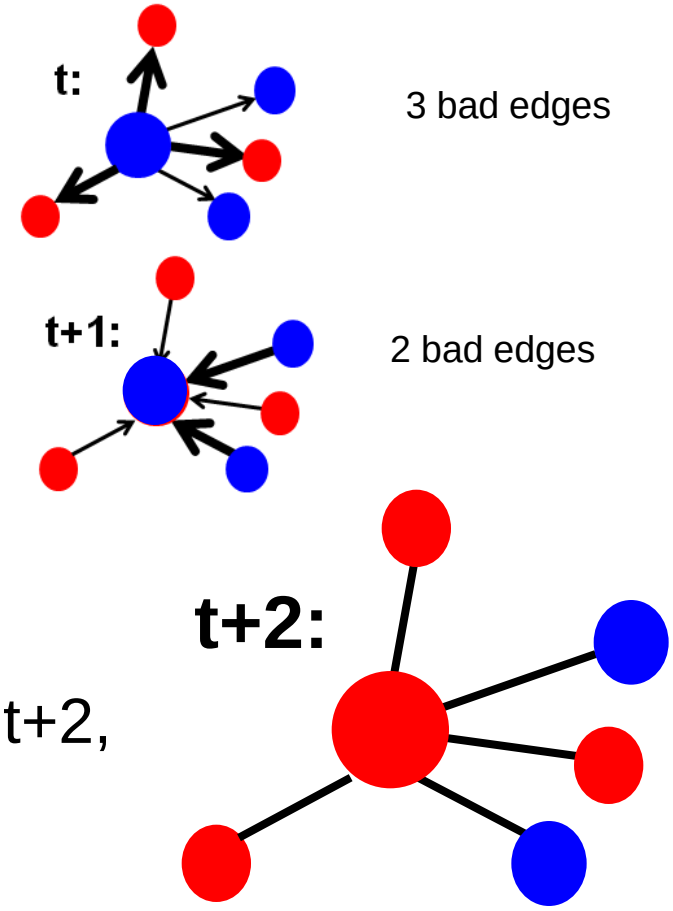
Democrats / Republicans

Eventually each citizen will vote for the same party every other day.

Continued (3)

- If g<b: citizen c will change its opinion on day t+2. (At time t+1? Unclear…)

- Note: The number of bad out-edges on day *t* is exactly the number of good in-edges on day *t*+1 (and vice versa).



If node chooses different party at t and t+2, number of bad edges decreases!

Democrats / Republicans

Eventually each citizen will vote for the same party every other day.

Continued (4)

- In both cases, the number of bad edges does not increase.
- In fact, it decreases if any node switches the party.
- Since the number of bad edges cannot be negative, the system will stabilize for a certain number of bad edges.
- Once number of bad edges stabilized, each node either stabilizes to a party or switches back and forth between times t and t+2.

QED

What kind of equilibrium is this?

- Is eventually everybody voting for the same party?
- Will each citizen eventually stay with the same party?
- Will citizens that stayed with the same party for some time, stay with that party forever?
- And if their friends also constantly root for the same party?
- Will this beast stabilize at all? ☺

What kind of equilibrium is this?

- Is eventually everybody voting for the same party? No.
- Will each citizen eventually stay with the same party? No.
- Will citizens that stayed with the same party for some time, stay with that party forever? No.
- And if their friends also constantly root for the same party? No.

Related to Conway's Game of Life

- Turing-complete game: LIFE
- 2d cell grid, each cell *dead* or *alive*
- Every cell interacts with its eight neighbors:
  - Any live cell with fewer than two live neighbors dies (loneliness).
  - Any live cell with more than three live neighbors dies, as if by overcrowding.
  - Any live cell with >2 live neighbors lives on to the next generation.

Can model complex things: gun + glider:
